Firm Value, Diversified Capital Assets and Credit Risk: Towards a Theory of Default Correlation

Lars Grüne*  Willi Semmler†  Lucas Bernard‡

June 19, 2006

Abstract

Following the lead of Merton (1974), recent research has focused on the relationship of credit risk to firm value. Although this has usually been done for a single firm, the growth of structured finance, which necessarily involves the correlation between included securities, has spurred interest in the connection between credit-default risk and the dependencies and cross-correlations arising in families of firms. Previous work by Grüne and Semmler (2005), focusing on a single firm, has shown that firm-value models, incorporating company-specific endogenous risk premia, imply that exposure to risk does impact asset value. In this paper, we extend these results to study the effects of random shocks to diversified capital assets wherein the shocks are correlated to varying degrees. Thus, we construct a framework within which the effects of correlated shocks to capital assets can be related to the probability of default for the company. The dynamic decision problem of maximizing the present value of a firm faced with stochastic shocks is solved using numerical techniques. Further, the impact of varying dependency structures on the over-all default rate is also explored.

1 Introduction

There is a long tradition of deriving security prices, e.g., stocks and bonds, from the value of a company’s assets. The general background literature goes back to Modigliani and Miller (1958), Black and Scholes (1973), and Merton (1974) where it is presumed that the asset value of the company is exogenously given by a Brownian motion at the time the company’s debt is priced. This is usually done by using the classic balance sheet equivalency: \( V = S + B \) where \( V \) is the asset value, \( S \) is the value of stocks, and \( B \) is the value of bonds. Furthermore, when short-term interest rates are given, one can derive the risk structure of interest rates.\(^1\)

Recent advances in the development of financial instruments have led to the recognition that the mechanisms by which companies borrow and, thus, generate credit risk, are quite complex. When combined together, a completely new set of phenomena is created, e.g., default frequency. The rise of CDOs and other structured financial products have greatly increased the interest in the correlation between default events occurring beneath a single umbrella. On the one hand, the grouping together of a number of entities creates an even more complex entity, on the other, it also allows for the use of macroscopic analysis, e.g., macro-factors underlying probabilities.\(^2\) It is largely this observation that has given rise to modern risk management, which is concerned with the evaluation and control of credit risk. However, we feel that there is still reason to examine some of the fundamental processes which must lie beneath the global phenomena.

In this paper, we focus on evaluating a company’s capital assets and credit risk in the context of a production oriented asset pricing model.\(^3\) In our paper, we consider the evaluation of the default risk of a company by solving a debt control problem treated as a dynamic decision problem. Using this construction, the solution of the dynamic decision problem gives us the company’s asset value. We then extend this method to include multiple capital assets which are subject to random shocks. In this way, we examine how the default probability might be related to the correlation of shocks to the different fractions of a company’s capital assets. Much as volatility has come to be the quoted variable in derivatives analysis, so correlation is becoming the quoted variable in structured finance.

Following the aforementioned tradition in asset pricing, in our first step, we show how the asset value of a company depends upon the default risk of the company. This will, in turn, be defined by the creditworthiness of the company.\(^4\)

\(^1\)For details see Merton (1974).
\(^2\)This is similar to the way in which the properties of temperature and pressure allow one to deal with the fundamentally chaotic movement of individual atoms; so too, certain broad statistical measures may allow for a systematic treatment of collections of risky securities without a complete understanding of the underlying processes.
\(^3\)Some preliminary thoughts on the relationship of credit and a firms’ capital assets can be found in Keynes (1967, ch. 12).
We will show that the key to the impact of debt finance on the company’s asset value is its impact on credit cost. Specifically, we will demonstrate that default risk varies with the internal decisions made with respect to the use of capital assets. Company behavior under external financial constraints has been studied in many papers. In this paper we study how external finance, e.g., default premia paid on bonds, impact investment and company value, in particular, the probability of default for a firm possessing diverse capital assets. We presume that all companies pursue dynamic investment decisions.

The above mentioned literature on asset pricing has not sufficiently considered the impact of default premia on the value of companies’ assets. It also tends to disregard the attempts that managers may make to internally hedge their company’s investments. Usually it is assumed that a company can undertake investment by borrowing from the capital markets at an \textit{ex-ante} capital cost up to the point where the discounted pay-off is equal to the present value of the company. Taking this as a benchmark case, we consider the pricing of a company’s assets in the cases where the company faces borrowing constraints or when the company faces an external finance premium due to collateralized borrowing. The external finance premium is, in this literature, often interpreted as a default premium reflecting company-specific default risk. It is the company specific default risk that will give rise to a risk-caused endogenous credit cost and thus an endogenously determined risk structure of interest rates in the sense of Merton (1974).

In the second step, we argue that the problem of managing a company’s risk profile, as defined in the company’s bond pricing, is essentially a problem of the optimal control of company debt, the dynamics and correlation between the diversified elements of its capital stock, and its asset value. Here too, default risk and default premia, in contrast to many other recent models, will be endogenized and made state dependent, thus allowing us to treat the overall default rate of the company’s bonds from the input side, i.e., that arising from the diversified capital assets.

In particular, we are interested in the relationship between the diversification present in a company’s capital assets and the resulting probability of default. In the finance literature, it is already well recognized that the value of stocks may not be independent of the valuation of the firm’s debt; for example see Hanke (2003, ch. 2). An important issue in computing the asset value of a company is the optimization problem of that company. Consumption-based asset pricing theory would argue that the objective of the company is to deliver a stream of dividends for the equity holder. The optimization problem of the company would then be to maximize the present value of dividends to the share holders. We show that in an environment with debt-financed investment, one should be interested in the asset value of the company and not solely in the equity value of the company relevant for the share holders. The work on pricing corporate liability has largely taken this tone since Merton (1974) and numerous empirical

\footnote{See Gaskins (1971), Judd and Petersen (1986), Gertler and Gilchrist (1994), and other literature cited.}
approaches have been pursued to infer, from time series data on equity values, the asset value of a company.\textsuperscript{5}

We also note that if we take the maximization of the equity value for the share holders as the optimization problem, it is obvious – since endogenous credit costs reduce the net income of the company before dividends are paid – that the equity value of the company will be affected by state-dependent default premia.

What is important in our formulation of the optimization problem is that the asset value of the company and the default risk will be affected not only by the sequence of optimal investment decisions (size of investment and allocation of resources) of a company, but that the default premia are impacted by the correlation of shocks to the diversified capital assets. We are dealing with a complicated constrained optimization problem; its solution will require advanced numerical methods.

As to our solution method we note that these rather complex models cannot be solved analytically. We will make use of numerical dynamic programming and a set-oriented algorithm to solve the different model variants. These methods are well suited to the study of problems wherein companies face imperfect capital markets and where the risk premia are endogenized and where there might be correlated risk to the company’s capital assets.\textsuperscript{6}

The remainder of the paper is organized as follows: Section 2 discusses the literature, while Section 3 treats some issues of default premia and asset pricing. Section 4 introduces the basic dynamic asset pricing model and sets forth the stochastic version for diversified capital assets. Section 5 discusses the numerical procedures. Sections 6 reports the detailed results from our numerical study on the different variants of the model. Section 7 concludes the paper. The appendix provides some technical comments on the derivation of the default probability.\textsuperscript{7}

\section{Related Literature}

Clearly, default risk is of great interest not only to bond holders, but to owners of equity as well. As residual claimants, they are strongly influenced by bond defaults. However, though simple to state, it is not immediately obvious either how to measure default risk or how to model it. On the one hand, the causes of default risk, from loss of competitiveness, to a weak economy, to corporate mismanagement, are many and often hidden within the company. As outlined in Crouhy, Galai, and Mark (2000) credit risk may also become manifest in a multitude of ways. From downgrades, actual defaults, and other company-specific factors to changes in market indices, general economic factors, and interest,

\textsuperscript{5}See, for example, Duan, Gauthier, Simonato and Zaanoun (2002). There, a survey of empirical methods is given on how to estimate the asset value of the firm using a time series analysis of its equity value.

\textsuperscript{6}A stochastic version of such a dynamic programming algorithm is used in Grüne and Semmler (2004a) where a consumption based asset pricing model is solved.

\textsuperscript{7}More details on the numerical methods can be found in the papers by Grüne and Semmler listed in the references.
exchange, and unemployment rates, both the causes and the manifestations of changes in credit conditions are complex. Nonetheless, ultimately, the issue of default risk boils down to the question of: "Is there sufficient asset value in the company to pay the obligations due?"

The problem of how to measure and manage default risk, in particular that associated with corporations is as old as the concept of the company itself. Prior to the 1950s, most techniques focused on traditional accounting and financial statement-analysis methods. Franco Modigliani was the first to place the problem within the theoretical context now recognizable as modern finance. Along with coauthor Merton Miller, Franco Modigliani (1958) rigorously proposed scaffolding for the exploration of the relationship between a company’s market value and its debt and equity financing. An explicit equivalency linking the value of a company to its financial structure, expressed in terms of bonds, equity, and derivative securities based on these was established.

The 1960s and 1970s saw an explosive growth in the use of equity options culminating with the founding of the Chicago Board Options Exchange, CBOE, in 1973. The ready existence of a liquid market for derivative securities allowed for new types of analysis. Black and Scholes (1973) realized that what market makers actually do is to take risk-neutral positions in the contracts they deal with and make their money off the bid-ask spread. Therefore, the price of an option is determined by the costs involved in creating a risk-neutral portfolio. Under this paradigm, it becomes clear that it is stock-price volatility that determines the prices for both puts and calls. In fact, for this reason, traders are just as likely to quote volatility as they are to quote price.

Merton (1974), one year later, utilized this same methodology, treating the value of corporate debt, from the perspective of derivative pricing, in order to study the risk structure of corporate bonds. The Modigliani-Miller (1958) and Merton (1974) results follow from the proposition that the capital structure does not affect the company’s asset value. Although, as shown in recent papers, applying Black-Scholes and option pricing, the stock price of the company can be impacted by the capital structure, yet the asset value, which is split up into stocks and bonds, is independent of the capital structure. Those results are, however, obtained by assuming an exogenous stochastic process, a Brownian motion, for the asset value, which does not originate, as we will argue later, from the solution of a dynamic decision problem of a company acting under constraints. In other words, because of the complexity of the underlying company’s value-debt dynamics, it is tempting to build models that do not depend upon them, i.e., to make no attempt to offer a causal explanation for the phenomena.

Credit spread models, for example, treat the problem by considering the spread between the interest rate on defaultable debt and that of similar maturity

---

8In other words, they guarantee a liquid market by maintaining fully hedged positions which they continually adjust to reflect market movements and sales of both sides of their portfolios.

9See Hanke (2003).
risk-free debt. The idea here is that the reason for the spread is that bond purchasers need to be compensated for the risk present in the former and that this will yield information about the probability of default. Jonkheurt’s (1979) paper is one of the first to discuss the credit spread approach, while Hull and White (2000) have a more recent treatment. Another popular approach is the intensity model. Whereas the company-value method attempts to link default frequency to fundamental processes related to the financial structure of a company, an intensity model only seeks to describe the statistical characteristics of these events. Thus, like the credit spread approach, it offers little explanation of the fundamental default process. Madan and Unal (1998) use intensity-based methods in their paper and Duffie and Singleton (1997) develop the topic within the context of factor models.

The rise of structured financial products, e.g., CDOs, wherein collections of risky products are grouped together, has greatly increased the interest in default correlation models. Through the use of copula functions and other methods, it is possible to relate the default dependency internal to complex products to a generalized correlation variable. This framework also allows for the discussion of correlated defaults within the context of both intensity and company value models. Douglas Lucas’ (1995) paper is one of the first to explicitly discuss the topic, whereas Schönbucher (2001) and Embrechts, Lindskog, and McNeil (2003) present more contemporary treatments. Das and Duffie (2005) present evidence on how default events definitely correlate to a greater degree than had been thought. In contrast, our study is interested in correlations between "input" variables, i.e., stochastic shocks to different elements of a company’s capital assets and how those shocks ultimately influence the probability of default.

For our study, we preferred to continue along the company-value approach suggested by the early work, mentioned above, numerically analyzed by two of ourselves, e.g., in Grüne and Semmler (2005), and made practical, through the widespread acceptance of Moody’s KMV model. Crouhy, Galai, and Mark (2000) provide an excellent overview of the many approaches that have been found effective by practitioners. In particular, they analyze the implementation of the company-value approach in the commercial sphere. Moody’s KMV (named for Kealhofer, McQuown, and Vasicek, cofounders of the KMV Corporation) model calculates the Expected Default Frequency (EDF) based on the company’s capital structure, the volatility of the assets returns and the current asset value. The model specifies the financial structure of the company in terms of assets, current debt, long-term debt, and preferred shares. Next, the default point (DPT), the asset value where the company defaults, is computed. It is assumed that this point is above the size of its short-term debt.
The distance-to-default, $DD$, is the number of standard deviations between the mean of the distribution of the assets value and the default point, where $E[V_{\text{growth}}] =$ Expected[asset value in 1 year], Default Point $=$ (short-term debt) $+ \frac{1}{2}$ (long-term debt), and $\sigma =$ (volatility of asset returns). The last stage in this procedure is to construct a large list of companies, calculate their respective $DD$s, and note the expected default frequency, $EDF$, as a function of $DD$. Thus an estimate of the $EDF$, based on valuation, capital structure, and the market as a whole is achieved. Thus, this model combines structural elements and historical data to estimate probability of default.

In our model, we will not use any actual data points, but will compute the probability of default using a numerical approximation of the corresponding Hamilton-Jacobi-Bellman equation. The details of this are discussed, in general in the appendix, and are found, in detail in Camilli and Falcone (1995), Camilli, et. al. (2006).

### 3 Default Premia and Asset Pricing

We are now in a position to discuss the background of the present project. Defining the value of the company’s assets by $V$ and debt by $B$, we have $B = F(V, t)$. On the maturity date $T$, one needs to have $V - B > 0$ with $B$ being the promised payment, otherwise the company will default. Thus, the debt payment at maturity date $T$ is
\[ F(V,T) = \min(V,B) \]

In terms of a Brownian motion one can write a change of the value of debt as

\[ dB = (\alpha_B B - C_B)dt + \sigma_B Bdz \]

with \( \alpha_B, \sigma_B \) and \( C_B \) constants. Since \( B = F(V,t) \), and given a Brownian motion for the value of the underlying asset, \( V \), by

\[ dV = (\alpha_V V - C_V)dt + \sigma_V Vdz. \]

A solution of the stochastic equation for the debt, \( B \), depending on the stochastic process for \( V \), can be obtained by using Ito’s lemma (see Merton, 1974).

Below in the context of a dynamic model, it will be shown that if there are no risk premia and the company issues debt at a risk free interest rate the debt value of the company is equal to its creditworthiness which will be proxied by the company’s asset value. Thus we have as maximum debt capacity \( B^* = V \). This will, however be different for an endogenous risk premium where the risk premia may depend on the extent to which the company is levered. Then, as shown below, we will have \( B^* = F(V(B^*)) \), which is a more difficult problem to solve.

On the other hand, as noted above, recently, in economic theory, there has been much work on imperfect capital markets and companies’ investments. Many dynamic models have been proposed where a company operates in an environment of imperfect capital markets. Here we keep the focus on companies that may face an idiosyncratic default risk and default premia that may effect a company’s optimal investment strategy.\(^\text{10}\)

It is frequently posited that borrowers face a risk dependent-interest rate which is assumed to be comprised of a market interest rate, e.g., the risk-free interest rate, and an idiosyncratic component determined by the individual riskiness of the borrower.\(^\text{11}\) This gives rise to risk premia that companies have to pay contingent on their net worth. In this paper, the impact of both the credit constraint as well as endogenous risk premia on the company’s optimal investment and asset value will be explored.

As to the justification of the default premium, we draw on the literature of

\(^{10}\)Investment models with credit market borrowing from imperfect capital markets can be found in Townsend (1979), Kiyotaki and Moore (1997), Bernanke, Gertler and Gilchrist (1999) and Miller and Stiglitz (1999). In these models, the impact of imperfect credit market borrowing and debt dynamics on economic activity is studied.

\(^{11}\)Recently, the theory of asymmetric information and costly state verification has been employed, e.g., Bernanke, \textit{et al.} (1999), where a risk premium is taken as endogenous by making the default risk dependent on net worth of the borrower.
asymmetric information and costly state verification.\textsuperscript{12} Such a premium\textsuperscript{13} drives a wedge between the expected return of the borrower and the risk-free interest rate. The premium is positively related to the default cost and inversely related to the borrowers net worth. Net worth is defined as the company’s collateral value of the capital stock less the agent’s outstanding obligations.\textsuperscript{14} We measure the inverse relationship between the risk premium (default premium) and net worth as follows:

\[ H(k(t), B(t)) = \frac{\alpha_1}{\alpha_2 + \frac{N(t)}{k(t)}} \theta B(t) \]  

(1)

with \( H(k(t), B(t)) \) the credit cost depending on net worth, \( N(t) = k(t) - B(t) \), with \( k(t) \) as capital assets and \( B(t) \) as debt. The parameters are \( \alpha_1, \alpha_2, \mu > 0 \) and \( \theta \) is the risk-free interest rate. In the analytical and numerical study of the model below we presume that the risk premium will be zero for \( N(t) = k(t) \) and thus, in the limit, for \( B(t) = 0 \), the borrowing rate is the risk-free rate. Borrowing at a risk-free rate will be considered here as a benchmark case.\textsuperscript{15}

Figure 2 depicts the equ. (1) with the external finance premium which arises if \( N(t) < k(t) \), yet note that different company’s could face a different slope of such a default premium cost function.\textsuperscript{16}

\textsuperscript{12}This literature originates in the seminal work by Townsend (1979), in which lenders must pay a cost in order to observe the borrower’s realized returns. This motivates the use of collateral in credit market models. Uncollateralized borrowing is assumed to pay a larger premium than collateralized borrowing or self-financing. The premium arises from the threat of bankruptcy, i.e., the costs of auditing, accounting, and legal, as well as the loss of assets arising from asset liquidation. In terms of observable variables, the premium the company has to pay is considered premium as arising from default risk.

\textsuperscript{13}As Gomes, et. al. (2002) show for a large class of models, one can expect the external finance premium, indeed, to be equal to the premium necessary to compensate lenders for the default risk. Gomes, et. al. (2002) measure the default risk by the spread of corporate bonds and T-bills. Another proxy is the relative size of external finance to capital, see Gomes, et. al. (2002).

\textsuperscript{14}See Bernanke, Gertler and Gilchrist (1999)

\textsuperscript{15}Another way to state the risk premium, and thus the risk structure of interest rates if there is debt with different maturity, is \( R(\tau) - \theta \) with \( R(\tau) \) the yield to maturity \( \tau \), see Merton (1974). Hereby \( R(\tau) \) is then implicitly defined as \( e^{-R(\tau)\tau} = \mathcal{E}(V(\tau)) \).

\textsuperscript{16}Note also that for each firm, bonds with different maturity could have different risk premia which we will, however, disregard here.
Default premia are endogenized in the way we have indicated in figure 2. The default risk creating an endogenous credit cost as well as upper borrowing constraints can affect the value of the company so that the net worth also becomes endogenous. Such a case can be studied using a modified HJB-equation and our new numerical methods. Moreover, we want to note that the risk-free rate does not need to be a constant, it could be stochastic and vary over time.\textsuperscript{17}

4 A Model with Endogenized Default Premia

We will present our model in two steps. In the first, we have a deterministic version with a single productive asset, while the second step allows for diversification of the company’s assets. In the latter case, depending upon which form of productive activity is being utilized, the productive assets are subject to random shocks. We thus imagine a company that is able to shift its resources across productive assets.

First, for the deterministic case, we specify the dynamic decision problem of a company that faces a default premia on its bonds as described in the previous section. In our model, as in Cochrane’s (1991, 1996), asset pricing can be studied without reference to utility theory or a discount factor obtained from the growth rate of marginal utilities.\textsuperscript{18}

\textsuperscript{17}For details of such a model see Grüne, Semmler and Sieveking (2004).

\textsuperscript{18}In Grüne, Semmler and Sieveking (2004), an analytical treatment is given of why and under what conditions the subsequent dynamic decision problem of a firm can be separated from the consumption problem.
In step one, the company accumulates a productive asset through an optimal investment where debt can be continuously issued and retired. In each period the company does not have to pay attention to the maturity structure of its debt and it does not face one-period borrowing constraints. Yet, there can be intertemporal debt constraints that affect the present value of the activity of the company.

Employing the risk premia as formulated in equ. (1), we study the following dynamic decision problem of a company accumulating a productive asset.

\[ V(k) = \max \int_0^\infty e^{-\delta t} f(k(t), j(t)) \, dt \]  
(2)

\[ \dot{k}(t) = j(t) - \delta k(t), \quad k(0) = k. \]  
(3)

\[ \dot{B}(t) = H(k(t), B(t)) - f(k(t), j(t)), \quad B(0) = B_0 \]  
(4)

The company’s net income

\[ f(k, j) = ak^\alpha - j - j^\beta k^{-\gamma} = ak^\alpha - j - \left( \frac{j}{k} \right)^2 \; \text{when} \; \beta = \gamma = 2 \]  
(5)

is generated from productive assets, i.e., capital stock, through a production function, \( ak^\alpha \); investment, \( j \), is undertaken so as to maximize the present value of net income given the adjustment cost of capital \( \phi(k, j) = j^\beta k^{-\gamma} \). Note that \( \sigma > 0, \alpha > 0, \beta > 1, \gamma > 0 \), are constants, equ. (3) represents the equation for the company’s productive assets, and equ. (4), the evolution of debt for the company, represented by outstanding bonds. Since net income in (5) can be negative, the temporary budget constraint requires the further issuance of bonds (further borrowing from credit markets) and, if there is positive net income, debt can be retired.

As shown above, we assume that the risk premium in our credit cost function \( H(k, B) \) may be state-dependent, depending on the productive asset, \( k \), and the level of debt \( B \) with \( H_k < 0 \) and \( H_B > 0 \). Note, however, that if we assume that the default risk depends inversely on net worth, as in equ. (1), we get a special case of our model where only the risk-free interest rate determines the risk premia.

\[ \text{Note that in order to recover the usual optimization problem for linear credit cost, we state our optimization problem in such a way so as to include the limiting case where there is a linear credit cost. However, our numerical procedure can solve the more difficult problem where there are state dependent default premia.} \]

\[ \text{The productive activity of the company can also be interpreted as written in efficiency labor, therefore} \; \sigma \text{can represent the sum of the capital depreciation rate, and rate of exogenous technical change. Note that in (3) a consumption stream could be included. In the study by Grüne, Semmler and Sieveking (2004) such a consumption stream is treated.} \]
credit cost. We then have a linear model with constant credit cost, $\theta$, and a state equation for the evolution of debt such as
\[
\dot{B}(t) = \theta B(t) - f(k, B), \quad B(0) = B_0 \tag{6}
\]

In this case, which we consider our benchmark case, we would only have to consider the transversality condition $\lim_{t\to\infty} e^{-\theta t} B(t) = 0$, as the non-explosiveness condition for debt, to close the model and equ. (2) would give us the company’s asset value.

Pontryagin’s maximum principle is not suitable for solving the problem with endogenous default premium and endogenous net worth. Thus, we need to use special numerical methods to solve for the present value and investment strategy of a levered company.

Ignoring time subscripts, for constant interest rates (no time-varying risk premia) the HJB equation for equs. (2)-(4), where $B^* = V$, may be written
\[
\theta V = \max_j \left[ f(k, j) + \frac{dV(k)}{dk} (j - \delta k) \right] \tag{7}
\]

In the general case of equ. (2)-(4), with company-specific default risk and the default premium as stated in equ. (1) and shown in Figure 1, we have the following modified HJB-equation instead:
\[
H(k, B^*(k)) = \max_j \left[ f(k, j) + \frac{dB^*(k)}{dk} (j - \delta k) \right] \tag{8}
\]

Note that in the limiting case, where there is no borrowing, $N = k$, and we have a constant discount rate $\theta$, we obtain the HJB-equation (7). The HJB-equation (8) can be written as
\[
B^*(k) = \max_j H^{-1} \left[ f(k, j) + \frac{dB^*(k)}{dk} (j - \delta k) \right] \tag{9}
\]

which is a standard dynamic form of a HJB-equation. Next, for example, let us specify $H(k, B) = B^* \theta$ where, with $\kappa > 1$ the interest payment is solely convex in $B$. We then get
\[
B^*(k) = \max_j \left[ f(k, j) + \frac{dB^*}{dk} (j - \delta k) \right]^{\frac{\kappa}{\theta}} - \frac{1}{\kappa} \tag{10}
\]

As can be shown for equ (10), with $\kappa > 1$, the same equilibrium emerges as for (7). The algorithm used to study the more general problem of equ. (9) is described in section 5.

Note that in the case of $\kappa > 1$, $B^*(k)$, equ. (8), will be smaller than $V(k)$, equ. (7). There is an additional default cost to be paid which is not present in equ. (6), the integral of which will drive a wedge between the present value $V(k)$ and $B^*(k)$. Thus, $B^*(k) < V(k)$ will hold.
Employing our general form for default premium\(^{21}\) \(H(k, B) \geq \theta B\), the debt capacity, \(B^*(k)\), relates to the asset value of the company for \(B(t) \leq B^*(k(t))\) as follows.

\[
V(k) = B^*(k) + V_H(k, B^*(k)).
\]

For the case \(H(k, B) = \theta B\) we have \(V(k) = B^*(k)\); for the case of an endogenous default premium \(H(k, B^*)\), where we have \(H(k, B^*(k))\), the debt capacity will be less than \(V(k)\). Yet, whenever \(B < B^*\) the value of the company’s assets can be represented by stocks and bonds, thus permitting a consumption stream for the owner of the stocks. Yet, as we have pointed out above, the company’s asset value may also be affected by the default premium.

The second step in our model expands upon the above to move closer to real-world situations. Here, the company’s total assets may be diversified into two different types of productive assets which may, in turn, be subject to correlated shocks. Thus, as concerns total assets and potential earnings, the weight, \(w\), devoted to one line of productive assets will be valued differently than that, \(1 - w\), devoted to the other. The following equation states that the total cash income to the company is generated by the respective portions in each productive asset minus the adjustment costs and reinvestment.

\[
f(k, j) = a_1(wk)^{\alpha_1} - (wj)^{\beta_1} + a_2((1-w)k)^{\alpha_2} - ((1-w)j)^{\beta_2} - \gamma_2 - j
\]

(11)

For example, we might imagine that the company allocates its productive assets at the beginning of each year and a decision is made as to which major productive activities should be undertaken. We presume that the company is able to shift its resources around in a fairly fluid manner, thus, it may change the percentage of its resources, \(w\), that are devoted to one activity or the other, \(1-w\), at will. Each productive activity is subject to random shocks. Prior knowledge of the markets yields information about the expected correlations between the different productive activities. Thus, a choice as to what to produce is made at the beginning of the year with respect to, among other things, correlation.

The company directors have two decisions to make:

1) What percentage of the company’s assets need to be channeled into product-A production, \(w\), and what percentage into product-B, \(1-w\).

2) What amount of revenues should be reinvested, \(j\), in the company as a whole.

Both decisions are undertaken in such a way as to maximize the present value of the company as seen from a discounted future income perspective. We assume that the amount of revenue thus generated will be dependant upon the relative weight of the overall resources that are devoted to the respective productive assets and to parameters specifically related to them.

\(^{21}\) For more details of the subsequent derivations, see Grüne, Semmler and Sieveking (2004).
Thus, there are two control variables, \( w \) and \( j \). The total assets, \( k \), will be influenced by the natural depreciation rate and by additional investment. Following the logic of our model, we further presume that equity is increased by retiring debt as quickly as possible. Thus, while positive cash flow may be used to pay off bonds or to reinvest in the company, negative cash flow will require the issuance of new bonds. Because of the complex way in which the random shocks effect the value of the company’s assets, depending also on whether it has been shunted into one or the other line of production, and because of the nonlinear way in which revenues are generated, the optimal decision path is not obvious.

We are interested in discovering how differences in the correlation between the shock processes effect the probability of default. Thus, our objective equation remains

\[
V(k) = \max_j \int_0^\infty e^{-\alpha t} f(k(t), j(t)) \, dt
\]

(12)

Small changes in capital are now the sum of the differences between mean reinvestment of cash inflows and depreciation (for each line of production) plus stochastic shocks, proportional to weight, to the productive assets invested in each line of production. So, the evolution of total productive assets can be described by

\[
dk(t) = (j(t) - k(t)(\delta_1 w + \delta_2(1 - w)))dt + k(t)(w \sigma_1 dX_1(t) + (1 - w)\sigma Y dY_p(t))
\]

and

\[
\frac{dB(t)}{dt} = H(k(t), B(t)) - f(k(t), j(t)) \, dt
\]

(13)

where \( Y_p \) is a process correlated, with coefficient \( \rho \), with the random process \( X_1 \). We can imagine that the company’s total assets have been invested in diversified capital assets that are subject to shocks in different ways.\(^{23}\) It is easy to generate two random variables with a specified correlation using the relation:

\[
Y_p = \rho X_1 + \sqrt{1 - \rho^2} X_2
\]

\(^{22}\)We note that this equation combines the evolution of two productive assets subject to correlated random shocks. Thus, there are two random, but correlated, processes that are both contributory:

\[
\begin{aligned}
\frac{dk_w(t)}{dt} &= k(t)w(\delta_w dt + \sigma_1 dX_1) \\
\frac{dk_{w-1}(t)}{dt} &= k(t)(1 - w)(\delta_{w-1} dt + \sigma Y dY_p)
\end{aligned}
\]

\(^{23}\)We might assume that the shock to the diversified capital assets comes through shocks to the market performance of those assets and are translated into shocks to the accumulated capital stock. Tobin’s \( q \) theory of investment could help us to explain why external shocks are transmitted to the capital assets.
where \(X_1\) and \(X_2\) are uncorrelated random numbers and \(\rho\) is the desired correlation. Thus \(X_1\) and \(Y\) are random variable with correlation coefficient \(\rho\).

Thus, in this second step, we are able to study the effect of different types of correlation between the disturbances, those to the fractions of the company’s assets devoted to one or the other productive activity, on the probability of default. As will be shown, this version reduces to base cases for appropriate choices for \(\rho\).

5 Numerical Solution Methods

A dynamic programming (DP) algorithm\(^{24}\) can be applied to solve the discounted infinite horizon optimal control problem of type (2)-(4). This is applicable when there is no default premium and no restrictions on the dynamics are present. For our model, this applies when the model is linear, i.e., \(H(k, B) = \theta B\) as in (9) and if in addition the constraint on \(B\) is given by \(\inf_j \sup_{t \geq 0} B(t) < \infty\), since in this case it follows that \(B^*(k)\) is easily obtained from \(V(k)\) in (2), namely from

\[
V(k) = \max_j \int_0^\infty e^{-\delta t} f(k(t), j(t)) \, dt
\]

We will briefly describe the algorithm, which goes back to Capuzzo Dolcetta (1983), Falcone (1987) and Grüne (1997). For details and for a mathematically rigorous convergence analysis we refer to the work by Bardi and Capuzzo Dolcetta (1997) and to Grüne, Metscher and Ohlberger (1999).

First, the continuous time optimal control problem is replaced by a first order discrete time approximation given by

\[
V_h(k) = \max_j J_h(k, j), \quad J_h(k, j) = h \sum_{i=0}^\infty (1 - \theta h)^i f(k_h(i), j_i)
\]

where \(k_h\) is defined by the discrete dynamics

\[
k_h(0) = k, \quad k_h(i + 1) = k_h(i) + h(j_i - \sigma k_h(i))
\]

and \(h > 0\) is the discretization time step. Note that \(j = (j_i)_{i \in \mathbb{N}_0}\) here denotes a discrete control sequence.

The optimal value function is the unique solution of the discrete Hamilton–Jacobi–Bellman equation

\[
V_h(k) = \max_j \{h f(k, j_0) + (1 - \theta h)V_h(k_h(1))\},
\]

\(^{24}\)For a further discussion of the dynamic programming algorithm and more detailed applications in economics, see Grüne and Semmler (2004).
where \( k_h(1) \) denotes the discrete solution corresponding to the control \( j \) and initial value \( k \) after one time step \( h \). Abbreviating

\[
T_h(V_h)(k) = \max_j \{ hf(k, j_0) + (1 - \theta h)V_h(k_h(1)) \}
\]

the second step of the algorithm now approximates the solution on a grid, \( \Gamma \), covering a compact subset of the state space, i.e., a compact interval \([0, K]\) in our setup. Denoting the nodes of \( \Gamma \) by \( k^i, i = 1, \ldots, P \), we are now looking for an approximation \( V^\Gamma_h \) satisfying

\[
V^\Gamma_h(k^i) = T_h(V^\Gamma_h)(k^i)
\]

for each node \( k^i \) of the grid, where the value of \( V^\Gamma_h \) for points \( k \) which are not grid points (these are needed for the evaluation of \( T_h \)) is determined by linear interpolation. We refer to the work cited above for the description of iterative methods. Note that an approximately optimal control law (in feedback form for the discrete dynamics) can be obtained from this approximation by taking the value \( j^*(k) = j \) for \( j \) realizing the maximum in (A10), where \( V_h \) is replaced by \( V^\Gamma_h \). This procedure, in particular, allows the numerical computation of approximately optimal trajectories.

In order to distribute the nodes of the grid efficiently, we make use of a posteriori error estimation. For each cell \( C_i \) of the grid \( \Gamma \) we compute

\[
\eta_i := \max_{k \in C_i} |T_h(V^\Gamma_h)(k) - V_h(k)|
\]

(more precisely we approximate this value by evaluating the right hand side in a number of test points). It can be shown that the error estimators \( \eta_i \) give upper and lower bounds for the real error (i.e., the difference between \( V_h \) and \( V^\Gamma_h \)) and hence serve as an indicator for a possible local refinement of the grid \( \Gamma \). It should be noted that this adaptive refinement of the grid is very effective for detecting thresholds, because the optimal value function typically fails to be differentiable in these points, resulting in large local errors and consequently in a fine grid.

For the more general model, i.e., if there is a default premium as defined by \( H(k, B) \) in (1) and/or restrictions of the type \( B/k \leq c \), the above DP-algorithm unfortunately is not applicable. Even though, in certain cases, a HJB-equation for a discrete time version of the problem is available, it is not clear whether the full discretization procedure described above leads to a valid and convergent approximation of the asset price and the present value borrowing constraint.

Hence we propose a different approach for the solution of this problem, based on a set oriented method for the computation of domains of attraction.\(^{26}\)

\(^{25}\) Actually, for the one-dimensional problem at hand it is possible to compute rather accurate approximations \( v^h \) also with equidistributed grid points. In higher dimensions the computational advantage of adaptive gridding is much more obvious, see, e.g., the examples in Grüne (1997) or Grüne et al. (1999).

\(^{26}\) For a more detailed description of the algorithm, see Grüne and Semmler (2005)
method relies on the following observation: For a given compact interval \([0, K]\) for the capital stock \(k\) one sees that there exists a constant \(c^* > 0\) such that \(B^*(k) \leq c^*\) for all \(k \in [0, K]\). We here denote \(B^*(k)\) as the borrowing constraint of the firm. Hence, for \(k \in [0, K]\) the condition \(\sup_{t \geq 0} B(t) < \infty\) can be replaced by

\[
\sup_{t \geq 0} B(t) < c^*.
\]

Hence both this constraint and the constraint \(B(t) \leq ck(t)\) can be expressed as

\[
B(t) \leq d(k(t)) \quad \text{for all } t \geq 0
\]

for some suitable function \(d\). In other words, the set of all initial values \((k_0, B_0)\) for which this constraint is violated is given by

\[
D = \left\{ (k_0, B_0) \left| \begin{array}{l}
\text{there exists } T > 0 \text{ such that } B(t(j)) \geq d(k(t(j))) \\
\text{for all } j \text{ and some } t(j) \in [0, T]
\end{array} \right. \right\}
\]

and the curve \(B^*(k)\) is exactly the lower boundary of \(D\). For details of how the domains of attraction are computed, see Grüne and Semmler (2005). Equipped with the above two algorithms the firm’s asset value and thus the maximum debt capacity \(B^*\) can be computed.

6 Results of the Numerical Study

Before discussing the results of the numerical analysis, we note that our first step may actually be considered a special case of our more general model (second step), i.e., one in which \(\nu\) is fixed at 0.5 and \(\rho = -1\). In this case, the random shocks to different productive assets exactly balance each other, on average, thus returning us to the deterministic case. Additionally, for \(\rho = 1\), we get the equivalent special case of a single random shock process. For all cases we specify the company’s technology parameters to be the same namely \(\sigma = 0.15\), \(A = 0.29\), \(\alpha_i = 0.7\), \(\beta_i = 2\), \(\gamma = 0.3\) and \(\theta = 0.1\), so that results do not differ because of different technology parameters.\(^{28}\) The results that we obtain, therefore, are solely attributable to the issuance of the company’s risky debt. The remaining parameters are specified below.\(^{29}\)

As for the numerical procedure, all examples were computed for different \(k\)'s in the compact interval \([0, 2]\), using the set-oriented method described in section 5, with control range \(j \in [0, 0.25]\).\(^{30}\) The dynamic programming algorithm uses the numerical time step \(h = 0.05\) and an initial grid with 39 nodes. The final

\(^{27}\)In any numerical method we must restrict ourselves to a compact computational domain, hence this restriction is natural in this context.

\(^{28}\)The technology parameter \(\alpha\) does not need to be as high to obtain multiple equilibria; sufficient nonlinearity in adjustment costs will also generate that result.

\(^{29}\)Note that we, of course, could choose another source of heterogeneity of company’s capital assets, namely by assuming different technology parameters for the company’s productive assets. This might be another line of research which we will not pursue here.

\(^{30}\)In all our experiments larger control ranges did not yield different results.
adapted grid consisted of 130 nodes. The range of control values was discretized using 101 equidistributed values. In order to generate the discrete time model \( \Psi \) we used an extrapolation method. For this, the range of control values was discretized using 51 equidistributed values. The domain covered by the grid was chosen to be \([0, 2] \times [0, 3]\) where the upper value \( \bar{B} = 3 \) coincides with the value \( c^* = 3 \), used in order to implement the restriction \( \sup_{t \geq 0} B(t) < \infty \). The initial grid was chosen with 1024 cells, while the final adapted grids consisted of about 100000 to 500000 cells, depending on the example. For this algorithm, the figures below always show the set \( E_T \) which approximates the present value curve \( V(k) \). Recall that the width of this set gives an estimate for the spatial discretization error.

### 6.1 Deterministic Version

First, we consider our deterministic formulation. In our benchmark case, debt is issued, but with no default premium. Thus, the credit cost is given by \( H(k, B) = \theta B \). In this case, we can use the DP algorithm in order to solve the discounted infinite horizon problem (2)–(4). Figure 3 shows the corresponding optimal value function representing the present value curve, \( V(k) \). The present value curve represents the asset value of the company for initial conditions \( k(0) \).

![Figure 3: Present Value of Company's Capital Assets](image)

\[ k^* = 0.966 \]

---

The debt control problem is solved whenever debt is bounded by the firm’s asset value, so that we have \( V - B \geq 0 \). The optimal investment strategy is not constrained and thus the asset value which represents the maximum debt capacity \( B^* \), is obtained by a solution for an unconstrained optimal investment strategy, represented by the present value curve in Figure 3. For initial values of the capital assets above or below \( k^* \), the optimal trajectories tend to the domain of attraction \( k^* = 0.996 \). For all of those different initial conditions, the debt dynamics remain bounded as long \( V - B \geq 0 \), thus allowing the company’s equity holders to exercise the option of retiring the debt. Any initial debt above the present value curve will be explosive and the company will not be able to pay its obligations.

For the more general case where a default premium is to be paid we used the following function to represent risk premia:

\[
H(k(t), B(t)) = \frac{\alpha_1}{\left(\alpha_2 + \frac{N(t)}{k(t)}\right)^\mu} \theta B(t)
\]

For the model (2)-(4) with a risk premium included in the company’s borrowing cost, it is not possible to transform the model into a standard infinite horizon optimal control problem. This results because debt is now an additional constraint on the optimization problem. Hence, we used the set-oriented method (as described in sect. 5) for the computation of domains of attractions and undertake experiments for different shapes of the credit cost function representing different alternative functions for the risk premium. An important class of functions for risk premia is defined by the steepness of the slope defined by the parameter \( \alpha_2 \).

For the above risk premium function we specify \( \mu = 2 \). Taking into account that we want \( \theta \) to be the risk-free interest rate, we obtain the condition \( \alpha_1/(\alpha_2 + 1)^2 = 1 \) and thus \( \alpha_1 = (\alpha_2 + 1)^2 \). Note that for \( \alpha_2 \to \infty \) and \( 0 \leq B \leq k \) one obtains \( H(k, B) = \theta B \), i.e., the model from the previous section.

Figure 3 shows the respective present value curves \( V(k) \) for \( \alpha_2 = 100, 10, 1, \sqrt{2} - 1 \) (from top to bottom) and the corresponding \( \alpha_1 = (\alpha_2 + 1)^2 \).
Figure 4: Present value curve $V(k)$ for different $\alpha_2$

For $\alpha_2 = 100$ firm’s asset value and the trajectories on the curve $V(k)$ show almost the same behavior as the ones in the previous section: There exists a threshold (now at $k(0) \geq k^*$) and where the company’s asset value converges toward and we have $k^{**} = 0.99$. This, as well as the other trajectories, demonstrate that the value function, and thus the company’s asset value, is smaller the larger the default risk resulting from low net worth. Thus, a state dependent default risk has the same effect on firm value as a higher discount rate in standard $q$-theory of investment. The debt capacity curve, $B^*$, moves down due to higher credit cost (higher default risk) and if the debt rises such that the debt constraint curve, $B^*(k)$, is reached, the net assets of the company shrink to zero; thus, $V - B = 0$ and no equity value claim on the net income stream of the firm can be supported.

7 The Stochastic Case

Next, we consider a stochastic version of our first model:

\[ \dot{k}(t) = (j(t) - \delta k(t))dt + \sigma k(t)dX(t) \] \hspace{1cm} (19)
\[ \dot{B}(t) = (H(k(t), B(t))) - f(k(t), j(t))dt \] \hspace{1cm} (20)

with $H(k(t), B(t))$ as defined as equ. (1), $\sigma$ the standard deviation and $dX(t)$ the Brownian motion. With $\delta_k = 0$ we recover the deterministic dynamics.
(3)-(4). The problem of asset and debt valuation as well as the controllability problem then becomes to steer the system to the set \( B \leq 0 \), i.e. to debt bounded in the long run. Using again our standard parameters of section 5, but \( \alpha_2 = 100 \), \( \alpha_1 = (\alpha_2 + 1)^2 \) and \( \mu = 2 \). Details of the numerical procedure are given in the appendix. With this graph, we have taken the \( k \times B \) plane of the previous two illustrations and added \( \Pr(\text{Default}) \), \( p \), as a third.

Figure 5: Numerically determined probabilities for \( \sigma = 0, \frac{1}{10}, \frac{1}{2} \)

Figure 5 shows the numerical results for \( \sigma = 0, \frac{1}{10} \) and \( \frac{1}{2} \). The case \( \sigma = 0 \) corresponds to our deterministic version, where the probability of no controllability and thus bankruptcy is just 0 or 1, and the line in the \([3, -0.5] \times [0, 2]\) plane is just our maximum debt capacity \( B^* = V \). As can be observed from the stochastic cases \( \sigma = \frac{1}{10} \) and \( \sigma = \frac{1}{2} \), the line of critical debt \( B^* = V \) moves down; thus, in a stochastic environment, the likelihood of bankruptcy is rising due to unexpected income shocks and the credit worthiness is shrinking.

However we will see interesting differences in the second case where we have diversifiable capital assets. We recall the equations of evolution for both debt and capital:

\[
dk(t) = (j(t) - k(t))(\delta_1 w + \delta_2(1 - w))dt + \sigma_1 dX_1(t) + \sigma_2 dY_\rho(t) \tag{21}
\]

\[
\dot{B}(t) = \theta B - f(k(t), j(t) - c(t)), B(0) = B_0 \tag{22}
\]

We first examine the case where \( w = \frac{1}{2}, \rho = -1 \)
Here, as anticipated, we recover the first case shown in figure 6. In this case, the two stochastic processes cancel each other out and we are left with a deterministic situation. In the next case, we consider $\rho = 1$. 

Figure 6: 50:50 Diversification, $\rho = -1$
Now we recover a case similar to the last case of figure 5. Since the two processes are exactly correlated, it is the same as having a single process.

In order to understand the next few graphs, we consider what happens if we let $w$ be a control variable. Considering the first diagram (above) for $B < B^*$, the deterministic system yields default probability $p = 0$ for $w = \frac{1}{2}$. Thus, the company managers will choose $w = \frac{1}{2}$ here. However, for $B > B^*$, the choice $w = \frac{1}{2}$ yields $p = 1$, thus deviating from $w = \frac{1}{2}$ can only decrease $p$; in other words, choosing $w \neq \frac{1}{2}$ introduces stochasticity to the system which increases the chances of surviving when $B > B^*$. We now consider a sequence with different correlation, $\rho$, between the productive assets and $w$ as a control variable.
Figure 8: Full Freedom to Diversify, $\rho = 1$

Figure 9: Full Freedom to Diversify, $\rho = 0$
Thus, in figure 10, we see that allowing the company’s managers the freedom to shift the weights of the productive assets enables them to not only maintain a large region of safety when $B < B^*$, but to also have only a gradual escalation of risk when $B > B^*$. Further, even at the extreme range of $(B = 3, k = 2)$, there is still a positive probability of solvency! This is because although the company may be close to insolvency in the deterministic case, the probability of a positive shock implies a possibility for survival.

8 Conclusions

In the paper we have examined a company’s default risk in the context of a dynamic decision problem where companies can borrow from the credit market for investment and where there is a risk premium which may be state dependent and the company is free to diversify its capital assets. The basis for the evaluation of credit risk and, thus, bond pricing is the firm-value approach, originally proposed in Merton (1974). Building on a production oriented asset pricing model we show that diversifying the capital assets enhances the borrowing ability of the company by decreasing its default risk. If risk premia, debt capacity (creditworthiness)$^{32}$ and asset value are endogenous, then the asset value of companies cannot be taken as exogenous when securities such as stocks and bonds

$^{32}$Our above analytical study of the debt control problem and suggests some methods of how to empirically evaluate sustainable debt, see Semmler (2003, ch. 4).
are priced. We used modern computational methods to solve the intertemporal decision problem and to compute the asset value of firms with endogenous risk premia. In the stochastic version with diversified capital assets, we allowed for correlated shocks to those capital assets and considered their impact on the company’s value and default probability. We also explored the impact of different diversification strategies and investment strategies. Finally, we want to note that our study suggests to reconsider the issue of the equity premium from the perspective of the default premium and internal hedging techniques.

9 Appendix

In order to explain the numerical algorithm for the computation of the probability of default, let us write the model in a general form, using the brief notation

\[
\begin{align*}
    dX(t) &= b(X(t), u(t)) \, dt + \sigma(X(t), u(t)) \, dW(t) \\
    X(0) &= x_0,
\end{align*}
\]  

(23)

with \( X(t) = (k(t), B(t)) \in \mathbb{R}^2 \). Then, defining \( K = \{(k, B) \in \mathbb{R}^2 \mid B \leq 0\} \) determining the minimal default probability amounts to computing the function

\[
p(x_0) := 1 - \inf_u \mathbb{P}\{X_t(x_0, u) \to K \text{ as } t \to \infty\}.
\]

In order to compute this function \( p \), consider the Hamilton–Jacobi–Bellman equation, called the stochastic Zubov equation,

\[
\sup_{u \in U} \{-\mathcal{L}(x, u) v(x(1 - v(x))) = 0 \}
\]  

(24)

for \( x = (k, B) \in \mathbb{R}^2 \). Here \( g \) is a continuous function with \( g(x) = 0 \) for \( x \in K \) and \( g(x) > 0 \) for \( x \notin K \) (we use \( g(x) = B^2 \) for \( B > 0 \) in our computations), \( \delta > 0 \) is a real valued parameter and

\[
\mathcal{L}(x, u) := \frac{1}{2} \sum_{i,j=1}^{2} a_{i,j}(x, u) \frac{\partial^2}{\partial x_i \partial x_j} + \sum_{i=1}^{2} b_i(x, u) \frac{\partial}{\partial x_i}
\]

denotes the generator of the Markov process associated to (23) where \( a_{i,j} \) are the entries of the matrix \( \sigma \sigma^T \).

It was proved in Camilli, Cesaroni, and Grüne (forthcoming) that (24) possesses a unique viscosity solution \( v_\delta \) depending on the parameter \( \delta > 0 \) which satisfies

\[
v_\delta(x) \to p(x) \text{ as } \delta \to 0
\]

In order to approximate \( p(x) \) we compute \( v_\delta(x) \) for \( \delta = 10^{-4} \) and perform a regularization and semi–discretization of (24) following Camilli, Grüne, and Wirth (2000) and Camilli and Falcone (1995)\(^{33}\).

\(^{33}\)See Grüne (2005) for details.
For regularization parameter $\varepsilon > 0$ and time step $h > 0$ (in our computations we used $\varepsilon = 10^{-4}$ and $h = 1/20$) this yields the equation

$$v(x) = \min_{u \in U} \mathbb{E}\{h\delta g(x) + (1 - h\delta g_{\varepsilon}(x))v(\varphi_h(x, u))\}.$$ \hspace{1cm} (25)

with

$$g_{\varepsilon}(x) = \max\{\varepsilon, g(x)\} \quad \text{and} \quad \varphi_h(x, u) = x + h b(x, u) + z \sigma(x, u),$$

where $z$ is a two-point distributed random variable which assumes the values $\pm \sqrt{h}$ with probability $1/2$ ($\varphi$ is the discretization of (23) using the simplified weak Euler scheme, cf. Kloeden and Platen (1999)).

Finally, using the techniques from Grüne (2005)34, we can use a dynamic programming algorithm in order to solve (25) on a grid with adaptive state space refinements.

34 Also see Grün and Semmler (2004a).
